## Abstract

*Arthrospira* (known commercially as Spirulina) is an edible cyanobacterium traditionally used for centuries as human food by various cultures. Its biochemical profile includes many bioactive molecules with enormous potential in human health. The aim of this paper is to systematically review the scientific evidence about the effects of dietary *Arthrospira* biomass consumption on a range of health outcomes. A search was made in PubMed and the Cochrane Library for randomised controlled clinical trials in which *Arthrospira* was used as a dietary supplement. An additional search was conducted for studies on rodents. Studies were organised by health outcomes. A total of 25 randomised clinical trials were included in the study. Four analysed the role of *Arthrospira* in dyslipidaemia, four in diabetes, one in hypertension, two in exercise, two in immune response, four in inflammation and precancerous lesions, and two in allergic rhinitis. Three studies analysed the antiviral effect of *Arthrospira* and a further three assessed its effect on nutritional status. For most of the targeted health outcomes in the selected clinical trials, daily consumption of *Arthrospira* biomass provided considerable benefits. However, more extensive studies that meet higher quality criteria are needed to confirm the reported results before any validated and absolute health claims can be made for this microorganism.

## Introduction

*Arthrospira* is an edible cyanobacterium traditionally consumed by some human civilisations (Ciferri 1983; Abdulqader et al. 2000). Spirulina is the commercial name of *Arthrospira platensis* and *Arthrospira maxima* (Tomaselli 1997), which were previously known as *Spirulina platensis* and *Spirulina maxima*, and which are commonly used as food, dietary supplements and feed supplements (Belay 2008). The rediscovery of *Arthrospira* and its biochemical properties in the 1960s led to mass production of microalgae for commercial purposes in the late 1970s and the development of an algae-based industry (Durand-Chastel 1980; Shimamatsu 2004; de la Jara et al. 2016).

*Arthrospira* is a source of amino acids, fatty acids, minerals and pigments. Its protein content is known to reach 60–70% of dry weight, with a profile that includes the full range of essential amino acids (Dillon et al. 1995). In addition, given the absence of a cellulosic cell wall, its protein digestibility can be as much as 83–90% compared to 95.1% for the standard casein (Falquet 1997).

*Arthrospira* has other important biochemical characteristics: for instance, its lipid profile contains palmitic, linoleic and  $\gamma$ -linolenic acid (GLA), which together account for 88–92% of the total fatty acid content (Mühling et al. 2005). The presence of GLA is important from the nutritional point of view because of its rarity in our daily food and possible prophylactic role in treating various chronic disease states (Fan and Chapkin 1998) such as atopic eczema, cyclic mastalgia, premenstrual syndrome, diabetes, cardiovascular disease, inflammation and cancer (Horrobin 1992). The pigments contained in *Arthrospira* are chlorophyll *a*,  $\beta$ -carotene, zeaxanthin, cryptoxanthin, C-phycoerythrin and allophycocyanin (Yan et al. 2011; Kumar et al. 2015) (Table 3), all of which are used by the organism to collect light for photosynthesis and protect it from photo-oxidative damage. Chlorophyll and its derivatives are well known; their bioactivity includes cancer prevention due to antioxidant and antimutagenic activity, mutagen trapping, modulation of xenobiotic metabolism and induction of apoptosis (Ferruzzi and Blakeslee 2007). Phycocyanin, its main pigment, is known to have potent antioxidant, anti-inflammatory, hepatoprotective and anticarcinogenic properties (Sekar and Chandramohan 2008; Soni et al. 2015). Other molecules such as sulphated polysaccharides are present in *Arthrospira* biomass. A compound known as calcium spirulan (Hayashi et al. 1996) has also been studied for its antiviral properties (Hayashi et al. 1993; Ayeahunie et al. 1998).

The bioactivity of all these compounds has been shown independently in many *in vitro* and *in vivo* studies. As this information reaches the market, *Arthrospira* and other microalgal supplements are chosen by consumers for nutritional, immune-boosting and detoxifying purposes (Rzymiski and Jaśkiewicz 2017; Wells et al. 2017). However, the question of the therapeutic or preventive roles of *Arthrospira* in most diseases remains controversial. Clinical trials are isolated and sometimes lack scientific rigour, e.g., in the use of inappropriate model systems or non-rigorous experimental design (Wells et al. 2017). Quality scales give readers a quantitative index of the likelihood that the reported methodology and results are free of bias (Moher et al. 1995) and therefore the lack of such quality restricts the use of claims regarding health, nutrient content and structure or function that are needed to fully develop an algae-based food industry (Grobbelaar 2003).

The main aim of this paper is to systematically review the current scientific evidence guaranteed by quality criteria about the effect of dietary *Arthrospira* whole biomass on a range of health outcomes in human trials. In order to identify targets for future validation in clinical trials, we also assessed studies on rodents. The final result will provide an overview of the current and potential roles of dietary *Arthrospira* consumption in human health.

## Material and methods

### Search strategy

One of the objectives of this study is to identify fields of human health in which the effect of dietary *Arthrospira* consumption has been addressed. A literature search was conducted to retrieve suitable clinical trials. It was considered important to include preclinical research on rodents, given that these results form the basic science knowledge that will be transferred to clinical applications.

The literature search for human studies was conducted in PubMed and Cochrane, and for studies on rodents (rats and mice) PubMed was used. Both searches were performed in June 2017. The medical subject headings (MeSH) of the National Library of Medicine were used to devise the key word search terms. The words, terms and combinations used were “Spirulina” plus “clinical trial”, “Spirulina” plus “rats” and “Spirulina” plus “mice”. In PubMed the term *Spirulina* includes the entry terms *Arthrospira*, *Arthrospira maxima* and *Spirulina maxima*.

### Data collection

For human studies, we collected items with no time restriction that met all the inclusion criteria: (a) human studies, (b) studies written in English and (c) studies using *Arthrospira* as a dietary supplement. We excluded reviews, congress abstracts, and clinical trials that had fewer than 10 participants, used pharmaceutical or botanical preparations with *Arthrospira* as an ingredient, or were based on *Arthrospira* extracts.

For rodent studies, selected items had to meet the following inclusion criteria: (a) mice or rat studies, (b) studies written in English, (c) studies using *Arthrospira* as a dietary supplement and (d) studies published in the last 10 years.

### Quality assessment

Three independent reviewers assessed the methodological quality of the studies identified. The full texts of articles for studies that met or appeared to meet the inclusion criteria were retrieved. The reference section in these papers was reviewed to identify relevant publications not captured electronically.

The Jadad scale was used to evaluate the quality of the studies, allocating a score from zero (very poor) to five (rigorous), based on randomisation, blinding and description of withdrawals (Halpern and Douglas 2005). Only studies meeting randomisation, blinding and control inclusion should be included in a systematic review. However, considering the lack of scientific rigour found in most of the studies, blinding was considered optional for inclusion. Results are summarised in Table 1.

**Table 1** Clinical trials used in the present study. Quality criteria were *R* randomisation, *B* blinding, *C* control; presence or absence were labelled + and –

## Results and discussion

Many in vitro and in vivo studies have evaluated the efficacy of various *Arthrospira* compounds in health (Deng and Chow 2010; Karkos et al. 2011). However, as far as we know, except for the meta-analysis by Serban et al. (2016) targeting the impact of *Arthrospira* supplementation on plasma lipid concentrations, there has been no systematic evaluation of the effect of *Arthrospira* biomass on health using clinical trials guaranteed by quality criteria such as double-blind, placebo controlled, randomised trials. To our knowledge, this study is the first systematic review to examine clinical trials on the effect of dietary supplementation with *Arthrospira* on human health that meet a quality scale criteria, specifically the Jadad scale criteria (Halpern and Douglas 2005).

### Health outcomes targeted in animal and human studies

A total of 154 studies were retrieved from the databases: 129 rodent studies (79 on rats and 50 on mice) and 42 human clinical trials. Flowcharts of the selection process for animal and human studies are shown in Figs. 1 and 2, respectively. Retrieved studies were classified by main outcome to target the major fields of action of *Arthrospira* in health (Figs. 3 and 4). We found that even though each study keeps to one main health target, outcomes could be found linked together. Lipid profile, for instance, was frequently included in trials targeting diabetes or immune response. Lipid parameters such as total cholesterol (TC), triglycerides (TG), low-density lipoprotein cholesterol (LDL-C) and high-density lipoprotein cholesterol HDL-C were the most prevalent outcomes (Table 2). Xenobiotic metabolism and oxidative stress was the most recurring field in animal studies, followed by inflammation, metabolic diseases, cancer, neuroprotection and immune response. Human studies focused on dyslipidaemia, hypertension and diabetes, which were grouped for this study as metabolic dysfunctions, exercise performance, immune response and ageing, inflammation and cancer, and allergy. The two groups (humans and animals) had common health targets, such as immune response, metabolism, virus control, allergy immune response, ageing, inflammation, cancer and nutrition.

**Fig. 1** Review process in rodent literature flowchart

**Fig. 2** Review process in human literature flowchart

Unexpectedly, the use of *Arthrospira* for nutritional purposes was poorly represented in both groups, even though this microorganism is considered an important protein source (Falquet 1997). The results show that most studies about the benefits of consuming *Arthrospira* have targeted its antioxidant bioactivity rather than its nutritional potential.

### Effect of *Arthrospira* in animal models

Animal studies outnumbered human studies (129 on animals, 42 on humans). The earliest study on rodents in the MedLine database is from 1988. Oxidative stress and xenobiotic metabolism was the field that returned the highest number of studies (56). These studies addressed the protective effect of *Arthrospira* biomass on organs, mainly the liver and kidney, based on its antioxidant protection against various substances including heavy metals (lead and cadmium) and tumorigenic compounds (nitroquinoline, organochlorides), and medication such as antibiotics (gentamicin), immunosuppressants (cyclosporine) and chemotherapy medication (cisplatin). Inflammation and metabolism,

including diabetes and hyperlipidaemia, with 21 and 19 studies respectively, are next in the ranking of studies on consumption of *Arthrospira* for disease prevention, followed by studies based on the protective action of *Arthrospira* against mutagenicity and teratogenicity (16), neuroprotection (7) and immune response (3). A common factor in these studies is the use of *Arthrospira* as a vector of antioxidant compounds. A small group was identified with the targeted fields of nutrition (3 studies), antimicrobial activity (1) and allergy (1) (Fig. 3). These findings support the hypothesis that the main benefit of consuming *Arthrospira* could be associated with the high antioxidant capacity of this organism rather than its use as a source of protein.

Animal models offer a wider range of possibilities for examining toxicity of interventions or studying disease pathology and mechanisms, whereas most clinical trials focus only on clinical efficacy (Hooijmans and Ritskes-Hoitinga 2013). This was confirmed in the present work, given that a high number of animal studies not only addressed the effect of *Arthrospira* on the organism, but also attempted to find the mechanism underlying the improvement in the disease. Because of the high number of works found on rodents only, it was decided simply to group them to assess the most common fields of study. However, it would be worthwhile carrying out an in-depth review of this information and making a critical appraisal of animal studies. A study of this kind could include a calculation of the human dose equivalent (HDE) to estimate the starting doses to prevent or treat serious pathologies in humans such as cancer, which, due to their vulnerable nature, are frequently addressed in animal studies but rarely in clinical studies.

**Fig. 3** Number of studies on the effect of *Arthrospira* consumption in rodents (rats and mice). White bars correspond to health outcomes related to the antioxidant capacity of *Arthrospira*. Black bars correspond to studies related to other properties of *Arthrospira*

### Human studies

The literature search identified 42 potentially relevant reports, from which 25 studies with a total of 2329 participants were selected for the systematic review. The earliest clinical trial in the database was from 1995. Studies were classified and grouped by health outcomes (Table 1). Eight studies were found on dyslipidaemia, seven on diabetes, two on hypertension, two on exercise, three on immune response and ageing, six on inflammation and precancerous lesions, and two on allergy. In other fields, four studies were retrieved for antiviral activity and eight for nutrition. However, only 25 of the 42 studies identified met quality standards and were systematically reviewed. Figure 4 shows the inclusion percentage of studies in the systematic review in their category after peering for quality criteria. Studies related to exercise and allergy were the most rigorous, followed by antiviral studies, whereas those on nutrition had the lowest quality criteria.

The information extracted from targeted studies on humans comprised author, publication year and country; study design; study size and participant characteristics (age, gender and inclusion/exclusion criteria); description of the intervention; follow-up period; outcomes and results (Table 2). Twenty works on the antioxidant effect of *Arthrospira* that met quality criteria were found. Four of these analysed its role in dyslipidaemia, four were on diabetes, two on hypertension, two on exercise, two on immune response, four on inflammation and precancerous lesions, and two on allergic rhinitis. A further three studies analysed the antiviral effect of *Arthrospira* and three others studied the effect of *Arthrospira* on nutritional status. Most works reported a positive response between *Arthrospira* consumption and improvement in the targeted health outcome (Table 2).

**Fig. 4** Percentage of studies included in the systematic review in their category

## Arthrospira consumption and oxidative stress-related diseases

Because oxidative stress is an inevitable result of life in an oxygen-rich environment (Davies 1995), aerobic organisms are fully equipped with mechanisms to prevent this type of stress. Certain compounds maintain equilibrium with pro-oxidants, giving rise to total antioxidant capacity (Ferrari 2012). When this equilibrium is lost because of increased exposure to high concentrations of reactive oxygen species (ROS) caused by alcohol, smoking, heavy metals, pesticides, electromagnetism, nuclear radiations or UV exposure, the cell is no longer capable of neutralising them and damage is caused. From the medical point of view, oxidative stress is linked to the prevalence of many human diseases such as neurodegenerative disease (e.g., Alzheimer's, Parkinson's and amyotrophic lateral sclerosis), inflammatory disease (e.g., rheumatoid arthritis), cardiovascular disease (e.g., muscular dystrophy), allergies, immune system dysfunction, diabetes, age-related diseases and cancer, all of which are increasing in prevalence. The influence of ROS may be detrimental to virtually all biomolecules (lipids, proteins and nucleic acids), resulting in structural and functional changes and eventually in necrotic or apoptotic cell death (Rizzo et al. 2009).

Using an exogenous source of antioxidant compounds to help the animal cell to neutralise the ROS level is feasible (Lobo et al. 2010). *Arthrospira* is known to have antioxidant properties, which are attributed to its biochemical profile containing phytopigments (Table 3), tocopherol,  $\gamma$ -linolenic acid and phenolic compounds (Chu et al. 2010; Lobo et al. 2010). *Arthrospira* consumption may play a role in preventing oxidative stress, but in our selection, only three studies explored the relation between *Arthrospira* consumption and oxidative stress using specific antioxidant biomarkers to establish this relationship (Table 2). Lu et al. (2006) found a higher significant increase in superoxide dismutase (SOD) after *Arthrospira* treatment (1324.09 to 1852.45  $\mu\text{Hb}$ ) ( $p < 0.01$ ) than with soy protein treatment (control group) (1251.1 to 1510.1  $\mu\text{Hb}$ ) ( $p < 0.05$ ). A study on obese and non-obese people (Park and Lee 2016) found a significant decrease in thiobarbituric acid-reactive substances (TBARS) (7.12  $\text{nmol mL}^{-1}$ ,  $p < 0.01$ ) in the non-obese group after *Arthrospira* consumption and a significant increase in total antioxidant status (TAS) (1.6 to 2.09  $\text{nmol L}^{-1}$ ,  $p \leq 0.01$ ) in the same group. Park et al. (2008) reported that after 16 weeks of *Arthrospira* consumption (8  $\text{g day}^{-1}$ ), TBARS decreased significantly in both males ( $p < 0.01$ ) and females ( $p < 0.05$ ) compared to the control group. A significant increase occurred in TAS in males (1.6 to 2.2  $\text{nmol L}^{-1}$ ,  $p < 0.01$ ) and in SOD (1.6 to 2.7  $\text{U mg}^{-1}$ ,  $p < 0.01$ ) in females. The study by Winter et al. (2014) included in the antiviral group also assessed antioxidant potential through the measurement of the total antioxidant capacity of the serum (TAOS). This value is reported

to provide an integrated index of antioxidant potential. In the placebo group, the authors found a decreasing value of TAOS ( $r = 0.48$ ,  $p = 0.008$ ) reflecting the progression of infection while the intervention group had a significantly increased effect on the TAOS ( $r = 0.51$ ,  $p = 0.007$ ) reflecting a possible rehabilitation of patients with initially low TAOS.

**Dyslipidaemia** Dyslipidaemia is an increase in plasma TG or LDL-C levels that contributes to the development of atherosclerosis, increasing the risk of cardiovascular events (e.g., myocardial infarction, ischemic stroke and death). Causes of dyslipidaemia may be primary (genetic) or secondary (e.g., lifestyle, sedentary routine, diabetes mellitus, excess alcohol, hypothyroidism, liver disease and drugs). It is estimated that prevalent cases of dyslipidaemia in the nine major countries (the USA, France, Germany, Italy, Spain, the UK, Japan, India and China) will increase at the rate of 1.76% a year to surpass 500 million in 2022 (Shi et al. 2014). Tóth et al. (2012) reported that the prevalence of standard lipid abnormalities among US adults is 53%, of which 27% have high LDL-C, 23% have low HDL-C and 30% have high TG. In addition, 21% of US adults have mixed dyslipidaemia, defined as the presence of high LDL-C combined with at least one other lipid abnormality. Nearly 6% of US adults have all three lipid abnormalities. Approximately 6.6% of adults have low HDL-C combined with hypertriglyceridemia. In China, the prevalence of dyslipidaemia in adults was estimated in a meta-analysis conducted by Huang et al. (2014) as 41.9% of adults with lipid abnormalities. Dyslipidaemia is closely associated with increased endothelial production of ROS. Clinical studies have documented strong positive associations between plasma levels of oxidative stress parameters and atherogenic lipoproteins in patients with cardiovascular disease (Rizzo 2009). Dyslipidaemia treatment involves dietary changes, exercise and pharmacologic therapy.

A meta-analysis of the impact of *Arthrospira* supplementation on plasma lipid concentrations (Serban et al. 2016) showed a significant effect in reducing TC, LDL-C and TG and raising HDL-C. This is consistent with our findings which retrieved eight interventions investigating the association between *Arthrospira* consumption and dyslipidaemia. All included lipid markers total cholesterol (TC), total triglycerides (TG), low-density lipoprotein (LDL-C) and high-density lipoprotein (HDL-C). In every case, the authors reported improvements in some of these parameters after *Arthrospira* treatment, mainly in TC and TG. However, only four of eight studies in this field met the quality criteria for systematic review.

Table 1 shows that the study by Zeinalian et al. (2017) was the most rigorous. The authors reported that obese individuals who were administered a dose of 1  $\text{g day}^{-1}$  of *Arthrospira* for 12 weeks had a significant reduction in body weight (BW), body mass index (BMI) and appetite compared to individuals who were supplemented with 1  $\text{g day}^{-1}$  of starch as control.

**Table 2** Summary of the clinical trials included in the systematic review of the effect of dietary *Arthrospira* in humans (IC inclusion criteria, EC exclusion criteria, DC discontinuation criteria, F/M female/male)

№	Study design	Sample population	Intervention	Control	Duration	Jadad score	Results
1	Randomised double-blind placebo-controlled trial	(n=56) IC: age= 20-50 years BMI ≥30 kg m <sup>-2</sup>  EC: kidney disease, atherosclerosis, cancer, acute infections, recent surgery, medication or supplements, pregnancy, lactation, menopause	(n=29) F/M: 24/5 <i>A. platensis</i> (1 g day <sup>-1</sup> )	(n=27) F/M: 23/4 <i>Starch</i> (1 g day <sup>-1</sup> )	3 months	3	VEGF: no changes observed after treatment in intervention or control Weight, WC, TG, LDL-C: decrease (non-significant) observed after treatment in intervention and control BMI: decrease (significant, p<0.01) in both groups: 1.9% after intervention, 0.73% in control group Appetite: decrease (significant, p<0.01) after intervention (4.16%) TC: decrease (significant, p<0.01) after intervention (4.67%) HDL-C: increase (significant, p<0.05) in both groups: 1.73% after intervention, 4.36% in control group
2	Randomised controlled trial	(n=61) IC: age= 20-50 years BMI ≥25 kg m <sup>-2</sup>  EC: Kidney disease, autoimmune liver disease, hemochromatosis, lung disease, virus infections, alcoholic fatty liver, diabetes, hepatitis B and C, dyslipidemia	(n=21) F/M: 11/10 <i>Chlorella vulgaris</i> (1 g day <sup>-1</sup> )  (n=20) F/M: 10/10 <i>A. platensis</i> (1 g day <sup>-1</sup> )	(n=20) F/M: 10/10 Control (nothing extra)	8 weeks	2	Better achievements in intervention groups compared to control. HDL-C: increase (non-significant, p >0.05) after interventions ( <i>Chlorella</i> and <i>Arthrospira</i> ) compared to control Weight: decrease (significant, p <0.05) after interventions ( <i>Chlorella</i> and <i>Arthrospira</i> ) compared to control TG: decrease (significant, p <0.05) after <i>Chlorella</i> intervention ALT, AST: decrease (significant, p <0.05) in control group compared with intervention groups
4	Longitudinal trial in a randomised cohort	(n= 169)  IC: HIV-infected antiretroviral adults naive to treatment. Mean age: 35.6±9 years  EC: CD4 ≤ 400 cell μL <sup>-1</sup> Lipid modifying therapies	(n=82) <i>A. platensis</i> (10 g day <sup>-1</sup> ) + fresh local balanced diet	(n=87) Fresh local balanced diet	6 months + 6-month follow up	1	BMI: decrease (non-significant) in intervention and control groups FBS: decrease (significant p <0.01), in intervention and control groups. After 12 months, significant decrease after intervention (from 105.89 to 95.35 mg L <sup>-1</sup> ) TG: decrease (significant, p<0.01) after intervention (from 206.9 to 123.5 mg dL <sup>-1</sup> ); increase (non-significant) for control TC: increase decrease (significant, p<0.01) after intervention (from 228.7 to 141.4 mg dL <sup>-1</sup> ); (non-significant) for control LDL-C: decrease (significant, p<0.01) after intervention (from 127.0 to 29.3 mg dL <sup>-1</sup> ); increase (non-significant) for control HDL-C: increase (significant, p<0.001) after intervention (from 48 to 100.98 mg dL <sup>-1</sup> ); increase (non-significant) for control AI: decrease (significant, p<0.0001) after intervention (TC/HDL-C: from 10.83 to 2.22 and LDL-C/HDL-C: from 8.24 to 0.96; increase (non-significant) for control

This dosage of *Arthrospira* partially modified serum lipids, significantly decreasing TC in comparison with the placebo. The authors also found an increase in HDL-C, but it was significant in both groups. The results were independent of age, gender or physical activity. Chitsaz et al. (2016) compared *Chlorella* and *Arthrospira* consumption to treat non-alcoholic fatty liver disease. They found that after supplementation of 1 g day<sup>-1</sup> for 8 weeks, anthropometric indices decreased significantly. Alanine transaminase values (ALT) were significantly different between intervention and non-intervention groups. The study by Ngo-Matip et al. (2014) also met randomisation and control inclusion and showed that supplementation with *Arthrospira* combined with a balanced diet can retard lipid abnormalities in immunosuppressed patients. In a study of HIV-infected people antiretroviral-naïve to treatment, they found a significant increase in HDL-C and a significant decrease in LDL-C and triglycerides in the group supplemented with 10 g day<sup>-1</sup> of *Arthrospira* for 6 months combined with a fresh local balanced diet, compared to the group that had only a balanced local diet. The atherogenic index (TC/HDL-C) also decreased significantly in the group supplemented with *Arthrospira*. Samuels et al. (2002) treated patients with hyperlipidemic nephrotic syndrome with either medication plus 1 g day<sup>-1</sup> of *Arthrospira* or medication only for 2 months. They found that TC and LDL-C decreased in both groups, with a higher significant decrease in the *Arthrospira* group. Triglycerides decreased in both groups but the decrease was significant only in the *Arthrospira* group.

Studies in other fields of this review which met quality criteria included lipid parameters in their outcomes, showing that *Arthrospira* consumption improves health status in terms of dyslipidaemia for seropositive diabetics (Marcel et al. 2011) and the elderly (Park et al. 2008). Marcel et al. (2011) observed a lower total-body fat and a downward trend for TC in the *Arthrospira*-treated group, although this group showed no significant differences in TC and TG levels.

**Diabetes** Oxidative stress also plays a key role in diabetes (Maritim et al. 2003) and its microvascular and cardiovascular complications (Giacco and Brownlee 2010). Pancreatic beta cells in type 2 diabetes are lost due to oxidation (Li et al. 2015). Free radicals are formed disproportionately in diabetes by glucose oxidation, non-enzymatic glycation of proteins, and subsequent oxidative degradation of glycated proteins (Maritim et al. 2003). HIV and HCV infections are both characterised by increased oxidative stress (Shin et al. 2012), which increases complications.

Seven studies analysing the effect of dietary *Arthrospira* in diabetes were retrieved, but only four met quality criteria. Serban et al. (2015) studied patients treated with metformin and placebo or metformin and *Arthrospira*. They found that after supplementation of 0.8 g day<sup>-1</sup> for 2 months, glycaemia

decreased significantly in both groups, although the decrease was higher in the *Arthrospira* group. The authors analysed the lipid profile and found that supplementation with *Arthrospira* did not improve the results compared with the medication group. Marcel et al. (2011) studied the effect of supplementation for 2 weeks with 5 g day<sup>-1</sup> of *Arthrospira* on insulin resistance in HIV-infected adult patients compared with soybean supplementation. They reported a significant increase in insulin sensitivity in the *Arthrospira* group despite a lower follow-up rate and fewer intake days (45 vs 59) in the *Arthrospira* group due to complaints about poor palatability. They also reported that *Arthrospira* seemed to be better than soybean at correcting HIV/HAART (human immunodeficiency virus/highly active antiretroviral therapy)-associated insulin resistance and concluded that *Arthrospira* supplementation may play a key role in HIV/HAART-associated insulin resistance. Lee et al. (2008) found that *Arthrospira* supplementation of 8 g/day for 12 weeks in patients with type 2 diabetes mellitus significantly lowered plasma triglycerides and plasma malondialdehyde level and increased plasma adiponectin. They also found that patients with higher initial total cholesterol and LDL-cholesterol showed higher reduction in plasma concentration of total cholesterol, LDL-C, interleukin-6 (IL-6) and blood pressure. Parikh et al. (2001) determined the efficacy of *Arthrospira* supplementation of 2 g day<sup>-1</sup> for 2 months. They reported an appreciable reduction in fasting blood glucose and postprandial blood glucose. A significant reduction in glycosylated haemoglobin (GH) was also found, indicating a long-term improvement in glucose regulation. In the lipids, triglycerides were significantly lowered, as were atherogenic indices (TC:HDL-C and LDL-C:HDL-C). An increase in the ratio of apolipoprotein A1 to apolipoprotein B was also observed.

**Hypertension** Earlier studies have shown that phycocyanin can ameliorate systemic blood pressure by enhancing endothelial nitric oxide synthase (eNOS) expression in the aorta (Ichimura et al. 2013). Two studies analysing the role of dietary *Arthrospira* in hypertension were retrieved, but only one met quality criteria.

Miczke et al. (2016) studied the effect of daily supplementation for 3 months with 2 g day<sup>-1</sup> of *Arthrospira* in patients with hypertension and obesity. They reported a significantly positive effect on systolic blood pressure and a tendency to decrease in diastolic blood pressure, suggesting a hypotensive and body mass reduction effect due to *Arthrospira*. The work by Lee et al. (2008), included in this review in the field of diabetes, also found a reduction in blood pressure after 3 months of *Arthrospira* supplementation.

**Exercise** Regular physical exercise has many health benefits, including a reduced risk of cardiovascular disease, cancer and diabetes. Paradoxically, it also promotes the production of

reactive oxygen and nitrogen species (RONS) (Powers and Jackson 2008), which contribute to muscle fatigue. In addition to the cellular strategies to regulate reactive species, such as superoxide dismutase, glutathione peroxidase and catalase, dietary antioxidants contribute to cellular protection against radicals and other ROS. Important dietary antioxidants include vitamin E, vitamin C and carotenoids, all of which are found in *Arthrospira* composition. Two studies in this field met the quality criteria. Lu et al. (2006) studied the preventive effects of *A. platensis* on skeletal muscle damage under exercise-induced oxidative stress induced by exhaustive exercise. They reported a significant decrease in malondialdehyde (MAD) levels and a significant increase in lactate (LA), SOD and time to exhaustion (TE) levels. A positive interaction between the parameters lactate dehydrogenase (LDH) and glutathione peroxidase (GPx) with time was found after administration of 7.5 g day<sup>-1</sup> of *Arthrospira*. Johnson et al. (2016) reported an anti-fatigue effect with short- and long-term *Arthrospira* intake.

**Immune response** Another important health outcome identified was immune response. The immune system has evolved to protect us from a universe of pathogenic microbes and toxins using a complex array of protective mechanisms to control and usually eliminate them (Chaplin 2006), as seen in the role of cytokines to control the behaviour of immune cells. Once activated, cytokines trigger other cells in the immune system, leading to a whole cascade of immune reactions. In healthy individuals, the immune system is self-regulated and once the threat disappears, the immune cells stop the inflammatory response via apoptosis. If this does not occur, chronic inflammation and even cancer may develop. In certain situations, such as advanced age or immunosuppressant diseases, numerous changes occur in the immune system, contributing to a decreased immune response (Ginaldi et al. 1999; McMichael et al. 2010).

Two of the three studies found in this field met the quality criteria for systematic review. Park and Lee (2016) studied the effect of *Arthrospira* supplementation on obese elderly people and found that a dosage of 8 g day<sup>-1</sup> for 12 weeks decreased lipid parameters and increased interleukin-2 (IL-2) and total antioxidant status level. They also reported a decrease in TBARS. Park et al. (2008) determined the antioxidant capacity, immunomodulatory and lipid-lowering effects of *Arthrospira* in healthy older people to examine the effectiveness of *Arthrospira* as a functional food in this stage of life. They reported that after 4 months of supplementation with 8 g day<sup>-1</sup> of *Arthrospira*, significant increases in IL-2 levels and superoxide dismutase activities occurred in female participants. Plasma levels of TBARS decreased 29% in males and SOD activity increased in females. With regard to immune variables, a significant rise in plasma IL-2 concentrations and a significant reduction in

IL-6 levels were found in males. Plasma TC levels also decreased in both genders.

Interleukin-2 is an anti-inflammatory cytokine essential in the regulation of chronic inflammation which, together with lipid peroxidation and dysregulated lipid metabolism, is a major characteristic of age-related changes. Although Park et al. (2008) did not find a significant reduction in the levels of proinflammatory cytokines such as tumour necrosis factor (TNF- $\alpha$ ), monocyte chemoattractant protein (MCP-1) or C3, it is likely that the sum of the downregulating effect of proinflammatory cytokines and improvement in other parameters improved the health of the population studied.

**Inflammation and precancerous lesions** Cancer prevention is another field in which *Arthrospira* could be beneficial. Reactive species damage DNA and its repair mechanism in a process that enhances ageing and carcinogenesis. Cancer cells exhibit accelerated metabolism and demand high ROS concentrations to maintain their high proliferation rate (Sosa et al. 2013). As the present review shows, the antioxidant compounds present in *Arthrospira* could be used to treat oral submucous fibrosis, a high-risk premalignant condition and reverse oral leukoplakias, both of which are well-known precancerous lesions. Animal studies have demonstrated the potential of *Arthrospira* in co-treatment of a range of malignant conditions. More studies in humans are needed, although conducting clinical trials on cancer treatment with natural products remains a sensitive issue. According to Paller et al. (2016), a likely explanation is that manufacturers of dietary supplements do not submit their products to the rigour and expense of a randomised, placebo-controlled phase 3 trial, which is required for therapy approval.

Six studies analysing the role of dietary *Arthrospira* in inflammation and precancerous lesions were retrieved, but only four met the quality criteria. All of them addressed the preventive effect of *Arthrospira* in oral precancerous conditions such as oral leukoplakias and oral submucous fibrosis. Patil et al. (2015) found that 0.5 g day<sup>-1</sup> of *Arthrospira* for 3 months improved certain symptoms (mouth opening and ulcers/erosions/vesicles). Zwiri et al. (2015) similarly administered 0.5 g day<sup>-1</sup> of *Arthrospira* for 3 months and compared the results with pentoxifylline administration. They observed improvements in all parameters for both groups, with clinical improvements in mouth opening and subjective symptoms of pain and burning sensation significantly higher in the *Arthrospira* group, while those treated with pentoxifylline had significant improvement in their ulcers, erosions and vesicles. In a similar study, Mulk et al. (2013) found significant improvements in mouth opening, burning sensation and tongue protrusion for both compounds after 3 months of treatment (0.8 g day<sup>-1</sup> pentoxifylline plus 1 g day<sup>-1</sup> *Arthrospira*). Comparing the effect of the two compounds, burning sensation was significantly improved after

pentoxifylline administration than with *Arthrospira*, but side effects such as stomach bloating, nausea and gastritis were reported to a greater extent after pentoxifylline treatment. Mathew et al. (1995) administered *Arthrospira* to participants with oral leukoplakia at a dosage of 1 g day<sup>-1</sup> for 1 year and found 45% complete regression of lesions compared to 7% in the placebo-treated group. They also observed a greater response in homogeneous than in nonhomogeneous lesions (erythroplakia, nodular/ulcerated and verrucous leukoplakia).

**Allergy** Allergic rhinitis is a worldwide affection. Between 10 and 30% of the population suffer this disorder and, according to the American Academy of Allergy, Asthma and Immunology, its prevalence is increasing globally due to several factors. Allergic rhinitis exerts a major impact on the quality of life of sufferers. Pharmacotherapeutic options include oral antihistamines and topical antihistamines that can be administered in the nose (Mullol et al. 2005), but the long-term effects of these medications cannot be declared completely safe (Paakkari 2002). Natural products could be useful to treat allergy while caring for the organism. Two studies analysing the role of dietary *Arthrospira* in allergy were retrieved and both met the quality criteria.

Cingi et al. (2008) evaluated the effectiveness of 2 g day<sup>-1</sup> of *Arthrospira* for 6 months in treating patients with allergic rhinitis. The symptoms evaluated were nasal discharge, sneezing, nasal congestion and itching. *Arthrospira* consumption significantly improved the evolution of symptoms and physical findings compared with placebo. Mao et al. (2005) found that at the same dosage, *Arthrospira* reduced production of IL-4, a cytokine involved in the induction of type I hypersensitivity that leads to the release of inflammatory mediators.

### **Arthrospira consumption and viral infections**

In the field of antiviral activity, many studies have used *Arthrospira* extracts. Hernández-Corona et al. (2002) assessed 50% effective inhibition doses (ED<sub>50</sub>) of *Arthrospira maxima* hot water extract against viruses such as herpes simplex virus type 2 (HSV-2), pseudorabies virus (PRV), human cytomegalovirus (HCMV) and HSV-1 (0.069, 0.103, 0.142, and 0.333 mg mL<sup>-1</sup>, respectively). For adenovirus, inhibition was less than 20%, and no inhibition was found for measles virus, subacute sclerosing panencephalitis virus (SSPE), vesicular stomatitis virus (VSV), poliovirus 1 or rotavirus SA-11. El-Baz et al. (2013) reported the antibacterial and antiviral effect of ethanol extract of *S. platensis* against non-enveloped RNA and DNA enteric viruses. Gustafson et al. (1989) observed remarkable in vitro activity of the sulfonic acid-containing glycolipids fraction of *Arthrospira* against HIV-1 virus. However, in the present study, antiviral activity is perhaps the field with the poorest results, because supplementation with whole dried biomass was unable to reduce the viral

load of HIV or hepatitis C in any of the clinical studies carried out in humans. Bioactive compounds may be found in higher concentrations in the extract than in whole biomass, explaining the difference in efficacy between the types of products. In the case of HIV-1, the mean level of CD38 on CD8+ cells is typically higher in HIV-positive untreated patients than in those on antiviral therapy and control because the level of CD8+ CD38+ T lymphocytes in blood correlates with disease progression in HIV-infected individuals, independently of the CD4 count (Benito et al. 2004).

Three of the four studies retrieved met the quality criteria. Two examined the role of *Arthrospira* consumption in HIV infections. Ngo-Matip et al. (2015) reported a significant increase in CD4 cell count and a significant decrease in viral load levels after 6 months of treatment with 10 g day<sup>-1</sup> *Arthrospira* supplementation plus usual diet during a 12-month study. Haemoglobin level was significantly higher in this same treatment group and fasting blood glucose concentration decreased after 12 months compared to control. Winter et al. (2014) studied the effect of 5 g day<sup>-1</sup> *Arthrospira* supplementation for 3 months on the viral load of people living with HIV/AIDS (PLHIV). They reported no difference between the immunological (CD4-T cell count) and virus markers (CD8 antigen expression) between the placebo group and the group supplemented with *Arthrospira*, although longer intervention periods could make a difference. Antioxidant capacity measured with the TAOS indicator (total antioxidant capacity of the serum) increased significantly in the *Arthrospira* supplemented group and decreased significantly in the placebo group. However, the intervention appeared to reduce the prevalence of concomitant events and opportunistic infections in both cases and showed a positive effect on patients' quality of life. Baicus and Tanasescu (2002) treated chronic viral liver disease or child A cirrhosis patients with 3.2 g day<sup>-1</sup> *Arthrospira* for 30 days. A greater decrease in aminotransferases occurred in the control than in the treated group. Although *Arthrospira* appears to improve markers of antioxidant capacity, no positive effects were found. These authors also assessed potentially toxic effects of *Arthrospira*, but found no significant modifications in haemoglobin, white blood cells, platelets, renal function or urinary sediments.

### **Arthrospira consumption and nutritional status**

Belay (2002) attributed initial interest in *Arthrospira* to its rich content of protein, vitamins, essential amino acids, minerals and essential fatty acids. Siva et al. (2015) found that significant studies have been done on *Arthrospira* to establish its potential use as a food supplement and food additive and to combat all forms of protein energy malnutrition (PEM) and protein energy wasting (PEW). Only three of the clinical trials retrieved met the quality criteria. Two of these were by Simporo et al. The first, published in 2005, assessed the

**Table 3** Pigments found in *Arthrospira* (extracted from Herrera et al. 1989)

Phytopigments	% dry weight
Phycocyanin	7.71
Chlorophyll- <i>a</i>	0.67
Carotenes	0.57

impact of an alimentary integrator composed of *Arthrospira* on the nutritional status of undernourished HIV-infected and HIV-negative children. They observed a decrease in the level of anaemia during the study in all children, although the level of recovery was less efficient among HIV-infected children (81.8% recovery in HIV-negative undernourished children compared to 63.6% in HIV-infected children). The second study, in 2006, assessed the impact of another alimentary integrator on the nutritional status of undernourished children in Burkina Faso. To test the effect of their proposed diet, anthropometrics and haematological parameters were compared after children aged less than 5 years old were given different meal combinations. The results revealed differences in weight increase: children in the group given Misola (millet, soya, peanut) plus *Arthrospira* showed faster weight correction. Li et al. (2012) studied the effect of *Arthrospira* as a dietary source of nutrients and found an increase in serum  $\beta$ -carotene and total-body vitamin A in children after 10 weeks of intervention supplemented with 2 or 4 g day<sup>-1</sup>. The studies that did not meet the quality criteria showed a significant improvement in children's HAZ after an intake of 10 g day<sup>-1</sup> of *Arthrospira* (Masuda et al. 2014); gains in height, weight, proteinograms and other biochemical parameters such as blood haemoglobin, serum ferritin, serum zinc and serum protein, and an increase in albumin levels in girls who took *Arthrospira* in India (Ramesh et al. 2013); and a greater increase in anthropometry and biochemical parameters such as leukocyte and lymphocyte number in HIV-positive children supplemented with *Arthrospira* than in HIV-negative children fed with traditional meals only (Simpore et al. 2005).

### Effect of size, dosage, gender, age and drop-out rate

Clinical trials must be carefully planned. According to Sakpal (2010), the basic rules for establishing the size of a clinical trial are level of significance, typically 5%; power, usually  $\geq 80\%$ ; clinically meaningful differences (smaller differences need a larger sample size); and a search for equivalence or equality. Small clinical trials should be carried out only in cases of rare disorders, unique patient populations or studies requiring participation of patients with terminal, severely debilitating or incapacitating disorders (Evans and Ildstad 2001). Because few studies were eligible for this systematic review, the sample size cut-off was established as  $n = 10$ , although smaller studies were also retrieved from the databases. Future clinical trials should pay particular attention to this

parameter, because it establishes the level of significance and the power of the study.

With regard to dosage, most of the health outcomes targeted in the clinical trials selected show significant benefits in daily consumption of *Arthrospira* biomass for a period varying from 1 to 12 months, with a mode of 2–3 months and a mean of 3.85 months with doses ranging from 0.5 to 20 g day<sup>-1</sup> with a mode of 1 g day<sup>-1</sup> and a mean of 7.5 g day<sup>-1</sup> (Table 2). Dosage was low in most of the works reviewed. Studies on diabetes, hypertension and nutrition applied the highest dosages. Two studies on nutritional status used dosages of 10 and 20 g day<sup>-1</sup> for children under 5 years, exceeding the ratio of *Arthrospira* intake (g)/weight (kg). The World Health Organisation (WHO) defined a safe level of protein intake for adults of 0.83 g kg<sup>-1</sup> day<sup>-1</sup>, irrespective of gender or age. The level is different for children and adolescents, varying from 1.31 to 0.89 g kg<sup>-1</sup> day<sup>-1</sup> from birth to adulthood depending on age, weight and height (WHO/FAO/UNU 2007). One gram of optimum quality *Arthrospira* would render 0.7 g of protein, which supports the theory of the current use of *Arthrospira* as a source of antioxidants rather than proteins. More studies are needed to assess the effect of dosage on outcomes.

Some studies included in the review found that *Arthrospira* bioactivity is gender- and age-dependent (Table 2). Improvements in the design and scope of studies would help to determine the correct dosage for a given health condition, gender and age group.

The drop-out rate was not excessively high in the studies. No adverse effects were recorded, which is not surprising given that the Dietary Supplements Information Expert Committee (DSI-EC) of the United States Pharmacopeial Convention (USP) assigned a class A safety rating for *A. maxima* and *A. platensis* after analysing 31 adverse event reports of *Arthrospira* to evaluate potential health concerns (Marles et al. 2011). The main concern expressed by patients was poor palatability.

### Quality, the key factor

#### i. Quality in clinical practice

*Arthrospira* is a safe and promising dietary supplement to prevent and even treat a range of health conditions, as demonstrated by many of the studies included in this review. However, much work is needed before this organism can occupy the position it deserves and be gainfully applied in nutrition and medicine. Laboratory findings must be translated into scientifically validated health claims to fill the gaps between scientific knowledge, medical practice and consumption habits. This can only be achieved through high quality, controlled clinical trials. The methodology exists, but consistent clinical trials are costly. The quality and scope of most of

the studies found was lower than expected. Only 25 of the 42 studies targeted were eligible for inclusion in the systematic review (Table 1, Fig. 4). The Jadad scale is one of the simplest quality scales in clinical practice (Berger and Alpers 2009), even though more than half the studies retrieved could not be used in the review (Table 1). The Jadad quality criteria (randomisation, blinding and control inclusion) should be the minimum requirements of future studies to ensure irrefutable scientific proof about the benefits of *Arthrospira*, because these results will become the health claims demanded by the food industry. The result of any systematic review is susceptible to selection bias, detection bias, implementation bias and publication bias. The trials included in this study are all randomised control trials but the variety of conditions addressed made a pooled analysis impossible. More accurate results could be obtained through a pooled analysis based on disease progress, course of medication and control group dosage.

## ii. Quality of *Arthrospira* biomass used as a supplement

Because the results of this review highlight the antioxidant capacity of *Arthrospira* as its major attribute in the treatment of various health conditions and diseases, the quality of the biomass is a key issue. Dosage is directly related to biomass quality. *Arthrospira* composition, as in all cyanobacteria and microalgae, is strongly affected by the production conditions (Colla et al. 2004; Mühling et al. 2005; Markou 2012; Kepekçi and Saygideger 2012; Kim et al. 2012) and processing (Morist et al. 2001, Tiburcio et al. 2007; Oliveira et al. 2010). Protein content in *Arthrospira* can be as much as 70% of dry weight (Uslu et al. 2009; Falquet 1997). C-phycoerythrin and allophycocyanin, the main antioxidants in *Arthrospira*, account for 20% of the protein fraction when this microorganism is cultured under optimum conditions (Avila-Leon et al. 2012). Mass production, dehydration and storage probably reduce the antioxidant content (Torzillo et al. 1984). The safety of *Arthrospira* has been a major concern for authorities. Now that safety guidelines have been established, the scientific and medical community and manufacturers and suppliers need to make a considerable effort to define biochemical quality standards for *Arthrospira* biomass used for therapy.

## Conclusion

To our knowledge, this study is the first systematic review to examine the effect of dietary supplementation with *Arthrospira* in various fields of human health. It reveals a variety of health outcomes that benefit from *Arthrospira* consumption. Most of the health outcomes targeted in the clinical trials selected showed significant benefits in daily consumption of *Arthrospira* biomass during a period varying from 1 to

12 months and doses of 0.5–20 g day<sup>-1</sup>. Some diseases, such as dyslipidaemia, improved by directly recovering proper values, while others such as diabetes and viral infections benefitted from a reduced prevalence of concomitant effects or increased immunity. Our findings also support the theory that the main benefit of *Arthrospira* consumption could be associated with the high antioxidant capacity of this organism, even though manufacturers and suppliers commercialise it as a protein source.

Large randomised, double-blind, placebo-controlled trials are needed before firm, unequivocal conclusions can be drawn about the suitability of *Arthrospira* to improve health conditions. Many variables must be taken into account, including biomass quality, dosage, gender and age. Achieving this will pave the way for more thorough studies that are essential to validate *Arthrospira* health claims.

**Funding information** This study was partially funded by the European Territorial Cooperation Programme PCT-MAC 2014-2020 through projects REBECA (MAC/1.1a/060) and MACBIOBLUE (MAC/1.1b/086).
